Department of Biomedical Engineering, University of Michigan, Ann Arbor, MI 48109, USA

ABSTRACT

Induced biomineralization of materials has been employed as a strategy to increase integration with host tissue, and more recently as a method to control cell function in tissue engineering. However, mineralization is typically performed in the absence of cells, since hypertonic solutions that lack the nutrients and culture components required for the maintenance of cell viability are often used. In the present study, we exposed fibroblast-seeded three-dimensional collagen–chitosan hydrogels to a defined culture medium modified to have specific concentrations of ions involved in biomineralization. The modified medium caused a significant increase in calcium deposition in collagen–chitosan gels, relative to constructs incubated in a standard medium, though serum supplementation attenuated mineral deposition. Collagen–chitosan constructs became opaque over 3 days of mineralization in modified Dulbecco's modified Eagle medium (DMEM), in contrast to translucent control gels incubated in standard DMEM. Histological staining confirmed increased levels of mineral in the treated constructs. Rheological characterization showed that both the storage and loss moduli increased significantly in mineralized materials. Mineralization of fibroblast-seeded constructs resulted in decreased cell viability and proliferation rate over 3 days of incubation in modified medium, but the cell population remained over 75% viable and regained its proliferative potential after rescue in standard culture medium. The ability to mineralize protein matrices in the presence of cells could be useful in creating mechanically stable tissue constructs, as well as to study the effects of the tissue microenvironment on cell function.

1. Introduction

There is a clear need for materials and methods to improve bone healing outcomes, particularly in cases of large defects and non-unions. The natural healing response is often not adequate to obtain full repair, and in such cases strategies to augment bone regeneration can be applied. Autografts and allografts are currently used clinically, but are hampered by issues of tissue availability and consistency [1]. The generic tissue engineering approach is to combine cells, biomaterials, and growth factors in a controlled fashion to create living materials that can replace damaged tissue and/or enhance regeneration. In the case of bone tissue, a wide range of strategies have been employed, using a variety of cell types, materials, and biochemical factors [2].

One strategy for potentiating the bone healing response is to use materials that have been exogenously mineralized using defined ionic solutions. Simulated body fluid (SBF) is a solution formulated with ion concentrations similar to blood plasma, which mineralizes the surfaces and pore walls of both natural [3–7] and synthetic [8–10] scaffolds if thermodynamic conditions are appropriate. Kokubo et al. [11] first described how soaking a biomaterial in SBF leads to the ex vivo formation of a bone-like apatite coating, and later studies showed that such coatings can be both osteoconductive [10] and osteoinductive [13], and can facilitate the regeneration of bone [12,14]. SBF-induced mineralization has been further examined as a method for controlling osteoconductivity [5,9,15], as well as for protein [13,16] and gene delivery [17,18]. Taken together, this body of work has shown that SBF can be a useful tool to modify biomaterials for bone tissue engineering applications.

Previous studies using SBF to modify material scaffolds have been performed in the absence of cells, since the high ionic concentrations and lack of nutrients in SBF are not conducive to the maintenance of cell growth. However, cell-seeded materials have been proposed for a number of orthopedic applications. Natural biomaterial hydrogels are of interest in such cases due to their ability to mimic the natural extracellular matrix [19] and provide tissue-specific cues to enhance cell attachment and stem cell differentiation [20]. Direct encapsulation of cells during gel formation can be used to facilitate homogenous cell distribution in hydrogels. Numerous natural polymers including collagen [3], chitosan [21], and

composite matrices [22–25] have been employed to engineer tissues and have shown promise in bone regeneration [26]. A drawback of natural hydrogel materials is that they often lack mechanical strength and represent only the protein component of the native bone tissue. Mineralization of such matrices has been pursued as a strategy to improve their mechanical properties and more closely mimic the native matrix [6]; however, the cellular component is typically not included during the mineralization process.

In the present study, we mineralized three-dimensional (3-D) hydrogels using a modified culture medium that combined the ionic constituents of SBF with the nutrients, vitamins, and amino acids needed to maintain cell viability. The model tissue constructs consisted of fibroblast cells embedded in collagen–chitosan hydrogel matrices developed previously in our laboratory [24,26]. Fibroblasts were used as a model cell type to examine the feasibility of mineralization in the presence of cells, since this non-mineralizing cell type allowed us to isolate the effects of mineralization to the medium alone. Both unseeded and fibroblast-seeded hydrogels were exposed to mineralizing solutions that were formulated to induce biomineralization while also supporting cell growth, and the effects of such treatment on mineral content, mechanical properties, and cellular viability were determined. Our primary goal was to demonstrate that mineralization of protein-based hydrogels is possible in the presence of cells. The ability to mineralize cell-seeded protein matrices could be useful in creating mechanically stable and osteogenic tissue constructs, as well as in studying the process of biomineralization.

2. Materials and methods

2.1. Media formulations

The composition of the mineralization medium was based on previously studied simulated body fluid (SBF) formulations, with modifications to enhance both mineralization and the ability to support cell growth. The base medium was Dulbecco's modified Eagle medium (DMEM; high glucose, Invitrogen, Carlsbad, CA), which was supplemented with ionic salts. Table 1 shows the ion concentrations of relevant biological fluids and mineralizing media. The main augmentation to the modified medium formulation was a fourfold increase in calcium (Ca^{2+}) and phosphate (PO_4^{3-}) in order to promote biomineralization, and an increased carbonate (HCO_3^-) level to provide buffering capacity. These modifications are further discussed in Section 3.

The modified medium (mDMEM) formulation was prepared by adding salts directly to DMEM to achieve final concentrations of 141 mM NaCl, 5.3 mM KCl, 10 mM $CaCl_2 \cdot H_2O$, 1.0 mM $MgCl_2$, 8.4 mM $NaHCO_3$, 0.8 mM $MgSO_4$, and 4.0 mM KH_2PO_4. The medium was prepared at 25 °C and titrated to a pH of 7.4. In experiments examining the effect of serum, mDMEM and control DMEM were supplemented with varying concentrations of fetal bovine serum (FBS; Invitrogen) and 1% penicillin/streptomycin (P/S; Invitrogen). As per previous protocols, mDMEM was changed every 12 h to avoid precipitation in the culture solution and DMEM

was changed every 3 days. In subsequent mineralization experiments using cells, the mineralization medium (MM) used was mDMEM supplemented with 2% FBS. The control medium (DM) was DMEM supplemented with 10% FBS.

2.2. Collagen–chitosan gel fabrication

Collagen–chitosan gel composites were formed through a β-GP induced mechanism as previously described [24]. Briefly, 4.0 mg ml^{-1} bovine Type I collagen (MP Biomedicals, Solon, OH) was dissolved in 0.02 N acetic acid (Sigma) and was mixed with 2.0 wt.% chitosan (93% DDA; Biosyntech, Quebec, Canada) dissolved in 0.1 N acetic acid at a mass ratio of 50/50 collagen/chitosan. Beta-glycerophosphate (β-GP) and glyoxal were added as physical and chemical cross-linkers, respectively, at concentrations of 7.0 wt.% β-GP and 0.5 mM glyoxal. A 400 μl aliquot of the pre-gelled mixture was injected into a well of a 24-well plate to create a disk-shaped construct with diameter of 1.5 cm. Gelation was then initiated by incubation of the mixture at 37 °C for 30 min. Gels were washed three times in phosphate buffered saline (PBS; Invitrogen) for 10 min to remove excess β-GP prior to use.

2.3. Calcium quantification

Calcium deposition on acellular gels after 3 days of incubation in either modified medium or DMEM containing 0%, 2%, 5%, and 10% FBS was quantified using an orthocresolphthalein complexone (OCPC) method as previously described [27]. Briefly, collagen–chitosan gels were washed three times in PBS for 10 min and frozen at days 0, 1, and 3. Samples were then digested in 0.5 ml of 1.0 N acetic acid overnight. 10 μl of the dissolved solution was then incubated at 10 min at 25 °C with 300 μl of a working solution consisting of 0.05 mg ml^{-1} of OCPC solution and ethanolamine/boric acid/8-hydroxyquinoline buffer (Sigma). Samples were read spectrophotometrically at 575 nm. Calcium values were quantified via a standard curve prepared from 0.0 to 100 μg ml^{-1}.

2.4. Gel morphology and von Kossa staining

Acellular gel morphology was examined 3 days after incubation in mineralization medium (MM = mDMEM + 2% FBS) and in control medium (DM = DMEM + 10% FBS). Gels were washed three times in PBS for 10 min each and then transferred to a 12-well plate for imaging using a standard CCD camera in manual mode with a constant exposure setting.

For von Kossa staining, acellular gels were washed three times in PBS for 10 min and then placed in zinc-buffered formalin (Anatech LTD, Battle Creek, MI) for 30 min, followed by immersion in 70% ethanol (Fisher Scientific, Pittsburgh, PA). Samples were cryosectioned into the top, middle (300 μm from the top face), and bottom face at the Histology Core Facility at the University of Michigan Dental School. Gels were stained with von Kossa reagent, embedded in paraffin and then mounted on slides. Images were taken at 4× magnification using an Olympus IX15 Microscope system (Olympus America, Center Valley, PA) and stitched together

Table 1
Ionic composition of biological fluids and media formulations.

	Na$^+$	K$^+$	Ca^{2+}	Mg^{2+}	HCO$_3^-$	SO$_4^{2+}$	HPO$_3^{2-}$	pH
Media formulation ion concentrations (mM)								
Blood plasma	142	3.6–5.5	2.1–2.6	1.0	27	1.0	0.65–1.45	7.2–7.4
Simulated body fluid (SBF)	141	4.0	2.5	1.0	4.2	0.5	1.0	7.4
Dulbecco's modified Eagle's medium (DMEM)	110	5.3	1.8	0	20	0.8	0.9	7.4
Modified DMEM (mDMEM)	141	5.3	10	1.0	8.4	0.8	4.0	7.4

using Metamorph Premier software (Molecular Devices, Sunnyvale, CA). Images were quantified using ImageJ software (National Institute of Health, Bethesda, MD) using thresholding and color discrimination to define positive staining. The ratio of the stained to unstained area was used to determine the fraction of the sample that was positively stained in each sample.

2.5. Gel rheology

Acellular collagen–chitosan constructs incubated in MM or DM for 3 days were washed three times in PBS for 10 min each and then evaluated by gel rheometry using an AR-G2 rheometer (TA Instruments, New Castle, DE). Gels were loaded onto a Peltier stage preheated to 37 °C. An 8 mm steel parallel plate was used with a gap height of 1500 μm. A strain sweep was performed over the course of 45 min with strain rates from 0.1% to 100% and a constant frequency of 1 radian s^{-1}. Reported values were taken over the linear range of the samples.

2.6. Cell culture and assays

Prior to gel fabrication, human neonatal dermal fibroblasts (hFbs; Lonza Inc., Walkersville, MD) were cultured in DMEM containing 10% FBS and 1% PS. For cell assays, hFbs were used at passage 7–9 and placed directly into the solution of collagen and chitosan at a concentration of 1.0×10^6 cells ml^{-1} prior to gelation, to allow for homogenous encapsulation within formed gels. Previous studies have shown that cells survive the encapsulation process [24,26], and hFbs were used in this study as a model cell type to isolate the effects of mineralization to the modified media solution.

Cell-seeded constructs in the MM condition were cultured for 1 day in DM, 3 days in MM, and then 7 days in DM for a recovery period. Samples were collected at days 0, 1, 2, 4, 5, 7, and 11 corresponding to initial conditions, 1 day in DM, 1 day in MM, 3 days in MM, 1 day's recovery in DM, 3 days of recovery in DM, and 7 days' recovery in DM (Fig. 1). Gels were washed three times in PBS for 10 min when switching between culture medium. Cell-seeded gels cultured in DM only were used as controls and samples were collected at corresponding time points.

To evaluate the toxicity of the MM media, cell viability was examined using a vital stain kit (Live/Dead®, Molecular Probes, Eugene, OR). Constructs were washed three times in sterile PBS and incubated at 37 °C for 45 min in a solution containing 4.0 μm calcein-AM and 4.0 μm ethidium homodimer-1 in PBS. Gels were then washed again in PBS and imaged using a laser scanning

Fig. 1. Experimental protocol showing timing of control cultures in standard DMEM (DM) and mineralizing cultures in modified DMEM (MM). All cell-seeded hydrogels were cultured in DM for 1 day. Mineralizing constructs were then incubated in MM for 3 days, followed by a 7 day recovery period in DM. Control constructs were incubated in DM for 11 days. Arrows on time scale indicate points at which constructs were sampled and analyzed.

confocal microscope (Olympus FluoView 500 Laser Scanning Confocal Microscope, Olympus). Image scans were captured at a horizontal plane 150 μm above the bottom surface of the gel and quantified using ImageJ software.

To quantify cell number during the mineralization period, DNA was extracted in 4.0 M guanidine hydrochloride solution and measured using a commercially available DNA assay (PicoGreen kit, Invitrogen). Calcium deposited on the constructs during the mineralization period was also measured using the OCPC assay described above.

2.7. Statistical analysis

One-way ANOVA testing with Tukey's post hoc analysis was used to analyze the effect of FBS concentration over time and between FBS concentrations on calcium deposition in acellular hydrogels. Student's *T*-test was used to assess the significance of the fractional area of von Kossa staining, rheological data, cell viability, DNA content, and calcium deposition in cell-seeded hydrogels treated with mineralizing medium, compared to control medium. One-way ANOVA with Tukey's post hoc analysis was used to analyze the effect of medium type over time on DNA content in cellular hydrogels. Statistical significance was set at $p < 0.05$. Numerical values are presented as mean ± standard error of the mean (SEM). $N = 4$ for each assay, and error bars on graphs represent the standard error of the mean.

3. Results and discussion

3.1. Rationale for media formulations

This work demonstrated the ability to mineralize protein biomaterials and change their properties in both the presence and absence of embedded cells. Mineralization techniques typically employ simulated body fluid (SBF); however, the lack of nutrients, vitamins, amino acids, and glucose prevent these media from being used for cell culture. DMEM is a commonly used medium for cell culture that can lead to the precipitation of mineral nodules on hydroxyapatite and tricalcium phosphate scaffolds in normal cell culture environments [28]. Therefore we used DMEM as a base medium and supplemented it with the specific salts to enhance the mineralization process. Table 1 shows the ion concentrations of SBF, DMEM, and mDMEM, as well as blood plasma for reference. The mineralizing DMEM (mDMEM) used in this study was formulated to have specific ionic concentrations aimed at maximizing mineral deposition [28]. mDMEM contained concentrations of sodium (Na$^+$), magnesium (Mg^{2+}), and sulfate (SO$_4^{2-}$) similar to conventional SBF. Calcium (Ca^{2+}) and phosphate (PO$_4^{3-}$) are the primary ions required for biomineralization, and were therefore added at concentrations approximately fourfold higher than conventional SBF to promote rapid mineralization of substrates. The carbonate (HCO$_3^-$) level was maximized to serve as a pH buffer in the media to allow culture in a CO$_2$ incubator, though this anion may be associated with decreased mineralization. Each of these solutions was adjusted to physiological pH to provide an appropriate environment for cell culture.

3.2. Effect of serum on calcium deposition

Serum is a necessary supplement in cell culture medium because it contains growth factors that maintain cell viability and growth [28,29]. However, in some systems serum proteins can detrimentally effect mineralization by delaying or inhibiting deposition [13,30,31]. To investigate the effect of serum on calcium deposition in collagen–chitosan materials, acellular hydrogel
Fig. 2. Calcium deposition in collagen–chitosan gels through incubation in mineralizing DMEM (mDMEM). (∗) denotes $p < 0.05$ from the groups containing FBS. Values are mean ± standard error, $n = 4$.

constructs were exposed to mineralizing DMEM supplemented with 0%, 2%, 5%, and 10% FBS. Gels incubated in control DMEM with 0%, 2%, 5%, and 10% FBS served as controls. Fig. 2 shows that calcium deposition increased significantly ($p < 0.01$) from day 0 in all samples incubated in mineralizing DMEM by day 1, and that mineralization continued to increase to day 3 in culture. In contrast, samples exposed to control DMEM showed no evidence of calcium deposition regardless of serum content or time point. In mDMEM samples, the presence of serum had no effect on the degree of calcium deposition at the day 1 time point, but by day 3 serum-supplemented samples showed decreased mineral deposition, relative to the sample with no serum ($p < 0.01$). There was no significant difference between 2%, 5% and 10% serum. These data show that FBS had an inhibitory effect on calcium deposition, but that mineralization did occur in the presence of serum proteins. Because of the need for at least a low level of serum for cell maintenance, mineralization studies conducted with cells were performed using mDMEM supplemented with 2% FBS as the mineralization medium (MM). The control medium (DM) was standard DMEM supplemented with 10% FBS, which is widely used for cell culture.

3.3. Mineralization of collagen–chitosan materials

Fig. 3 shows data on mineralization and mechanical properties of acellular collagen–chitosan matrices incubated in MM and DM for 3 days. Histological evaluation of von Kossa stained sections taken at the top, middle, and bottom of the constructs showed clear differences in degree of phosphate deposition between mineralizing and control conditions (Fig. 3A). After 3 days in incubation, constructs in DM remained translucent, whereas those in MM were opaque, and dark staining for calcium was more prominent in MM samples (Fig. 3A inset). Quantification of relative phosphate staining showed that hydrogels in MM exhibited significantly higher phosphate levels at the top and middle of the constructs, though staining in the bottom section was not statistically different compared to constructs in DM. These results support the finding that MM induces mineralization, but show that mineral deposition was not evenly distributed through the material.

Fig. 3B shows the storage (G') and loss (G'') modulus from acellular collagen–chitosan gels exposed to DM or MM for 3 days. Relative to control gels, mineralized gels exhibited a threefold increase in stiffness as reflected by the storage modulus ($p < 0.05$). The loss modulus also increased significantly ($p < 0.001$) in the MM condition, as compared to the DM condition. These data show that the mechanical properties of hydrogel constructs can be augmented by mineralization, even over relatively short time periods. SBF

Inset shows control and mineralized collagen constructs (top row, scale bar = 1 mm) and representative histology sections (bottom row, scale bar = 500 μm). (B) Storage (G') and loss (G'') moduli for control and mineralized collagen–chitosan constructs after 3 days of culture ($n = 4$, ∗ denotes $p < 0.05$ from the control DM group).

treatment can affect the properties of scaffolds, though the effects can vary depending on the distribution of the mineral throughout the scaffolding material [8,18]. Increasing the stiffness and toughness of protein hydrogel materials is desirable in order to allow implantation of constructs, particularly in load-bearing applications. A stiffer matrix may also attenuate the cell-mediated matrix remodeling that occurs in 3-D protein hydrogels [32], and may direct the phenotype of progenitor cells toward an osteogenic phenotype [33].

3.4. Effect of mineralization on cell function

Viability data for hFbs embedded in 3-D collagen–chitosan materials are shown in Figs. 4 and 5A. Green staining indicates the cytoplasm of living cells, whereas red-stained nuclei identify dead cells. The culture protocol is shown schematically by the arrows in Fig. 4. Control constructs were cultured in DM for 11 days, whereas mineralized constructs were cultured in DM for one day, followed by 3 days of incubation in MM, and then 7 days of culture recovery in DM. All samples were imaged and assayed for cell function at days 1, 2, 4, 5, 7, and 11. After one day of culture in DM, cells began to spread through the collagen–chitosan matrix (Fig. 4A and B) and exhibited very high viability (>90%). Constructs subsequently exposed to MM showed significantly decreased viability ($p < 0.05$) over the incubation period in MM (days 2 to 4, Fig. 4D and F), but viability was still high (∼80%). The morphology of cells incubated in MM was more rounded than the control cells, which were highly stellate and exhibited viability over 90% (Fig. 4C and E). Upon reintroduction into standard medium, cells in the mineralized constructs recovered a
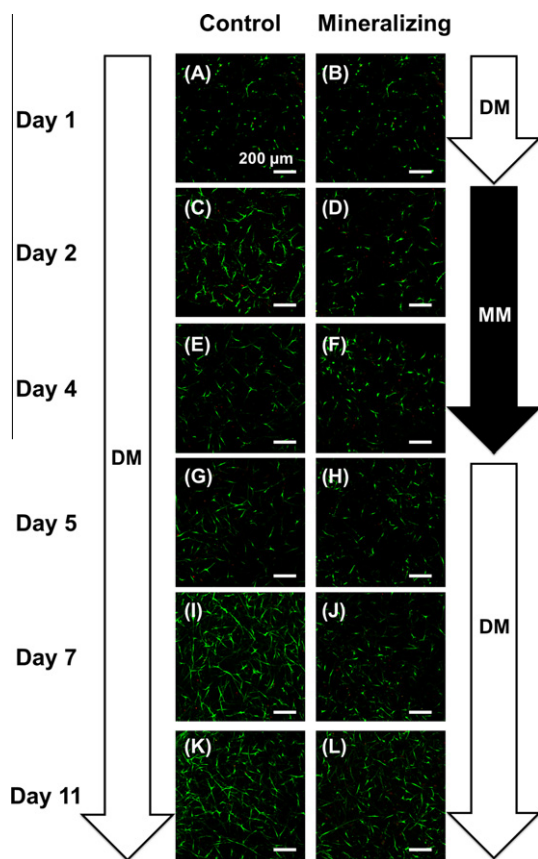

Fig. 4. Confocal micrographs of fibroblast-seeded collagen–chitosan gels cultured in control medium (A, C, E, G, I, K) or under mineralizing conditions (B, D, F, H, J, L). Cells are stained so that the cytoplasm of living cells is green and the nuclei of dead cells are red. Arrows at sides show culture protocol. Scale bar = 200 μm.

Fig. 5. Quantification of (A) cell viability ($n = 4$), (B) DNA content ($n = 4$), and (C) calcium content ($n = 4$) of collagen–chitosan constructs cultured in control and mineralizing medium (# denotes statistical significance from day 0 controls; ∗ denotes statistical significance from DM controls; ^ denotes statistical significance from day 7).

spread morphology (Fig. 4H, J and L) and viability returned to the same level as in control constructs by day 11 (>90%).

The DNA content of hydrogel constructs was used as a measure of cell number and is shown in Fig. 5B. Cell number increased steadily and significantly ($p < 0.001$) over time in the DM condition, resulting in an approximately fivefold increase by day 11. Constructs in the mineralization group showed an initial rise in DNA content, which subsequently dropped significantly upon incubation in MM from days 2 to 4 ($p < 0.0001$). Similar to cell viability, cell number in mineralized constructs recovered after transfer to DM, although the DNA content did not recover to the same levels as controls. The cell viability and cell number data provide different but complementary information on cell "health" in the constructs. A lack of cell proliferation would lead to a decrease in overall cell number over time, though viability observed as a snapshot at any given time can still be high, as observed in MM at the days 1 and 2 time points. Cell death is suggested by the data at the days 4 and 5 time points, since both viability and cell number were decreased. In contrast, when cells are proliferating then cell number will increase and viability can also be high. This corresponds to the trends observed in DM. Taken together these data suggest that incubation in mineralizing medium significantly reduces, and perhaps completely inhibits, the proliferation of the embedded cells while cell viability is also affected but remains high overall.

Fig. 5C shows calcium deposition in cell-seeded constructs over the time course of the experiment. Upon transfer to MM at day 2, constructs in the mineralizing group showed a sharp and significant increase in calcium content and reached a level ~140-fold higher than controls after 3 days of incubation in MM ($p < 0.001$). The calcium levels remained similarly high after transfer to recovery medium for the remainder of the experimental period. In contrast, constructs cultured in control medium (DM) showed very little calcium deposition, though a statistically significant increase over day 0 was observed at days 7 and 11 in DM ($p < 0.001$).

Fibroblasts were used as a model cell type in this study in order to isolate the effects of the modified medium. Unlike bone marrow stromal cells and osteoblasts, fibroblasts are a non-mineralizing cell type and therefore increases in mineral content of the matrices can be attributed purely to the effect of the medium, and not cellular action. Preliminary studies showed that hFbs could survive 3 days of incubation in MM, though longer culture periods lead

to increased cell death (data not shown). In 3-D collagen–chitosan hydrogels, cell viability and proliferation rate decreased over 3 days of incubation in MM, but the cell population remained over 75% viable. These effects can be attributed to the hypertonic nature of MM, which is required to induce mineralization but can also modify cell function. Importantly, both the viability and proliferative capacity of fibroblasts recovered when collagen–chitosan constructs were cultured in standard DMEM after mineralization. These results suggest that the medium and protocol employed were sufficient to mineralize 3-D protein constructs in the presence of living fibroblasts, and it is likely that similar results would be observed with other cell types.

A number of further questions remain to be answered in future studies. The specific structure and type of mineral being deposited is of interest because it has relevance to creating biomimetic materials. In addition, it is known that the presence of mineral, either as a substrate or in solution, can affect differentiation of progenitor and stem cells. The influence of material stiffness on cell phenotype is of great interest in the field of tissue engineering, and mineralized matrices may provide a tool to examine such effects. While the biochemical and mechanical effects of matrix mineralization can be difficult to decouple, the ability to mineralize 3-D protein-based materials may be another tool to study the effects of the tissue microenvironment on cell function. In addition, creating mineralized matrices in the presence of cells may be used to direct progenitor cell differentiation and/or to create more mechanically stable biomimetic constructs for orthopedic and other applications.

4. Conclusions

This study represents an initial step in the development of techniques to mineralize 3-D protein constructs in the presence of living cells. A modified culture medium and protocol were developed to achieve mineralization of collagen–chitosan matrices at physiological pH and temperature. Typically used SBF formulations do not support cell viability and growth and therefore are limited in their utility in the presence of cells. The modified medium used in this study contained a similar panel of mineralizing ions similar to SBF, though at modified concentrations, and also contained the nutrients and buffers needed to sustain cell function. It was shown that 3 day incubation of 3-D collagen–chitosan materials resulted in mineral deposition and stiffening of the gels. Cell viability was reduced and cell number decreased during incubation in mineralizing medium; however, a viable cell population was maintained and it was shown that viability and proliferation recovered after rescue in standard medium. These results suggest that in vitro mineralization in defined media can be used to modulate the composition and properties of engineered tissues in the presence of living cells.
